A Thesis Submitted to the Faculty of the
DEPARTMENT OF ELECTRICAL AND COMPUTER ENGINEERING
In Partial Fulfillment of the Requirements
For the Degree of
MASTER OF SCIENCE
WITH A MAJOR IN ELECTRICAL ENGINEERING
In the Graduate College
THE UNIVERSITY OF ARIZONA
1994
STATEMENT BY AUTHOR

This thesis has been submitted in partial fulfillment of requirements for an advanced degree at The University of Arizona and is deposited in the University Library to be made available to borrowers under rules of the Library.

Brief quotations from this thesis are allowable without special permission, provided that accurate acknowledgment of source is made. Requests for permission for extended quotation from or reproduction of this manuscript in whole or in part may be granted by the head of the major department or the Dean of the Graduate College when in his or her judgment the proposed use of the material is in the interests of scholarship. In all other instances, however, permission must be obtained from the author.

SIGNED: _________________________________

APPROVAL BY THESIS DIRECTOR

This thesis has been approved on the date shown below:

______________________________  ____________________
William H. Sanders                   Date
Associate Professor of
Electrical and Computer Engineering
To my family, and especially Anna,

for their continuous support and belief in me.
ACKNOWLEDGMENTS

There are a number of people to whom I owe thanks for their help and support during work on this thesis. First, I thank my graduate committee members, Dr. Michael Marcellin, Dr. Aad P.A. van Moorsel, and my advisor Dr. William Sanders, for reviewing my thesis. Bill deserves special thanks for his guidance throughout the project.

I would also like to thank the PMRL group for their help and friendship. In particular, thanks to Anand Kuratti for helping me through the complexities of the thesis process, and Aad for his thorough readings and helpful discussions.

ABSTRACT

Computation of transient state occupancy probabilities of continuous-time Markov chains is important for evaluating many dependability and performability models. Numerical methods have been developed to perform this computation, including ordinary differential equation solution methods and uniformization, however, their performance degrades with increasing model stiffness. A newly proposed variant of uniformization, adaptive uniformization (AU), can potentially avoid such degradation. This thesis presents results of three AU implementations, differing in the method by which the “jump probabilities” are calculated. Evaluation of these methods is carried out through use of a C++ class that computes a bound on the round-off error incurred, and counts the number of arithmetic instructions performed. Several example models illustrate use of the class and compare the adaptive uniformization implementations with standard uniformization. Results show that for certain models and mission times, adaptive uniformization can realize significant efficiency gains over standard uniformization, while maintaining the stability of standard uniformization.
CHAPTER 1

INTRODUCTION

Continuous-time Markov chains are often used to evaluate the performance, dependability, and performability of computer systems and networks. For many models [6, 7], transient measures are of particular interest. Since for large problems, closed-form solution is infeasible, numerical approaches are used. These include ordinary differential equation methods such as Runge-Kutta-Fehlberg or an implicit method TR-BDF2 [24], Jensen’s method [11] (commonly known as uniformization), and combinations thereof [15].

Uniformization has often been considered the best method [9, 10, 25] for computing transient state probabilities of continuous-time Markov chains, but suffers a dramatic degradation in performance as the highest state departure rate increases for any fixed time point [15]. For these so-called “stiff models,” the truncation point needed to achieve acceptable accuracy becomes prohibitively large. Adaptive uniformization (AU) [18] was introduced to avoid this problem in models where states with high transition rates are not reached for several state transitions, and is particularly applicable for models with short mission times, where ordinary differential equation methods are inefficient. Additionally,
AU shares a nice feature with uniformization in that an error bound can be prespecified, and computes an absolute lower bound result within the specified error. Adaptive uniformization takes advantage of the fact that there is typically a single initial state, and several transitions are necessary until all states are reachable, or active. Thus the uniformization rate at each step need only be greater than or equal to the largest outgoing rate from the set of currently active states, not greater than the largest rate in the entire state space. This allows bigger jumps to be made, reducing the number of iterations necessary to reach a solution.

While adaptive uniformization will always take a number of iterations less than or equal to standard uniformization to achieve a specified level of accuracy, most iterations require more computation, so it is not clear when AU will be computationally advantageous. Theoretical results [18] suggest that there are situations when this will be the case, but no implementations have been made that show that this is indeed true, or the magnitude of savings (or expenses) that may be incurred. In this thesis, results of three different implementations of adaptive uniformization are presented, and are compared with regular uniformization. The three implementations differ in how the “jump probabilities” are calculated, the most critical part of the adaptive uniformization algorithm.

In order to make a careful assessment of the various implementations, a C++ class was developed to instrument the code. This new class calculates a bound on the round-off error incurred by each method, and the number of floating point operations required for solution of a model. The number of operations is broken down by operation type (i.e., multiplication, division, addition, and subtraction) and by the portion of the algorithm...
the operations are associated with. The fine-grained nature of this data collection permits a clear understanding of the exact costs of the different portions of each algorithm, as well as when it will encounter numerical difficulties.

The objectives of this thesis are three-fold. First, three AU algorithms are implemented to be compatible with *UltraSAN* [2], a software package with which it is possible to model systems graphically as stochastic activity networks (SANs) [20]. From this graphical description, *UltraSAN* is capable of generating a CTMC and the associated reward structure. However, this thesis focuses only on the resulting CTMC and its transient solution. Second, it intends to show that it is indeed possible to instrument such algorithms to gain a clear understanding of exact costs and numerical issues of different algorithms. The *C++* class developed to do this is algorithm independent, and can be easily added to any algorithm implemented in *C* or *C++*. Finally, given the above, this thesis provides an accurate comparison, using the instrumented code, of the three adaptive uniformization implementations and standard uniformization in the context of several example models. The results show the advantages/disadvantages of the new approach are clearly problem dependent, but that there are realistic situations where adaptive uniformization is dramatically more efficient than SU, while retaining the stability of standard uniformization.

The thesis is organized as follows. After the theoretical background of uniformization and adaptive uniformization is reviewed in the next chapter, the details of computing the jump probabilities for AU are given in Chapter 3. Three methods, ACE [23], a modified ACE algorithm [18] and uniformization, are discussed in the context of the implementations. This chapter also explains modifications to the Fox and Glynn Poisson probability
calculation, and compares and describes the overall algorithm implementation. Chapter 4 explains the C++ class for evaluating the viability of the methods and results. Chapter 5 details results based upon instrumentation, empirically comparing uniformization and adaptive uniformization. Finally, Chapter 6 summarizes the thesis results and presents ideas for further research.
CHAPTER 2
BACKGROUND

This chapter explains the theory behind the methods used in this thesis to solve for the transient state probabilities of continuous-time Markov chains (CTMCs). Let CTMC $Y = \{Y(t); t \geq 0\}$ be defined on the state space $S$ where it is assumed $S = \{0, 1, 2, \ldots\}$. Let $Q = (q(i,j)), i, j \in S$, be the infinitesimal generator matrix of $Y$, with $q_i = -q(i,i)$ for $i \in S$. The row vector $\pi(0) = (\pi_0(0), \pi_1(0), \ldots)$ denotes the initial probability distribution of $S$. The objective is then to obtain the transient state probability vector $\pi(t)$, with $\pi_i(t) = \text{Prob}\{Y(t) = i\}$ for any $i \in S$. Only numerical techniques will be discussed, since closed-form solution for models having over 400 states is extremely difficult [32].

Kolmogorov’s differential equations [4] show that $\pi(t)$ follows

$$\frac{d\pi(t)}{dt} = \pi(t)Q, \text{ given } \pi(0).$$

(2.1)

Therefore, this problem has the solution $\pi(t) = \pi(0)e^{Qt}$. However, directly solving $e^{Qt}$ does not lead to satisfactory numerical algorithms [8, 16].
2.1 Standard Uniformization

In standard uniformization (SU), which is often used in the context of Markov models, the CTMC is decomposed into a discrete time Markov chain (DTMC) and a Poisson process [1]. For later use, standard uniformization is briefly reviewed. Let \( \lambda \geq \max \{q_i\}, i \in S \), be the so-called uniformization rate. Then, the DTMC \( X = \{X_n, n = 0, 1, \ldots\} \), can be defined, with transition matrix \( P = I + (1/\lambda)Q \). \( \pi(t) \) is then obtained from

\[
\pi(t) = \pi(0) \sum_{n=0}^{\infty} e^{-\lambda t} \left( \lambda t \right)^n n! P^n.
\] (2.2)

By introducing \( \bar{\pi}_n = \bar{\pi}_{n-1} P, n = 1, 2, \ldots \), where \( \bar{\pi}_0 = \pi(0) \), Equation 2.2 can be written recursively as

\[
\bar{\pi}(t) = \sum_{n=0}^{\infty} U_n(t) \bar{\pi}_n
\] (2.3)

where for later use the jump probabilities \( U_n(t) \) have been defined as

\[
U_n(t) = e^{-\lambda t} \left( \lambda t \right)^n / n!.
\] (2.4)

\( \bar{\pi}_n \) is interpreted as the state probability distribution of \( X \) after \( n \) state transitions. Thus \( \bar{\pi}(t) \) can be thought of as the discrete probability vector after \( n \) jumps multiplied by the probability of having \( n \) transitions occur, summed over all possible number of jumps. In SU, these jump probabilities form a Poisson distribution. Notice the recursive definition of Equation 2.3 allows the use of sparse matrix techniques for \( Q \) and \( P \). In this implementation of SU, the infinite sum of Equation 2.3 is both left and right truncated so that

\[
\bar{\pi}(t) \approx \sum_{n = N_{sl}}^{N_{sr}} e^{-\lambda t} \left( \lambda t \right)^n n! \bar{\pi}_n/n!.
\] (2.5)
and 
\[ \sum_{n=0}^{N_{st}-1} e^{-\lambda t} \frac{(\lambda t)^n}{n!} + \sum_{n=N_{sr}+1}^{\infty} e^{-\lambda t} \frac{(\lambda t)^n}{n!} < \epsilon. \] (2.6)

\( N_{st} \) and \( N_{sr} \) are then selected so that the resulting truncation error is less than an \( \epsilon > 0 \).

Notice that this left truncation does not affect the number of matrix-vector multiplications that must occur and only reduces the amount of summation necessary. It can then be seen, with \( \| \pi \|_\infty = \max \{|x_i|\} \), that
\[ \left\| \left( \sum_{n=0}^{N_{st}-1} e^{-\lambda t} \frac{(\lambda t)^n}{n!} + \sum_{n=N_{sr}+1}^{\infty} e^{-\lambda t} \frac{(\lambda t)^n}{n!} \right) \pi_n \right\|_\infty \leq \sum_{n=0}^{N_{st}-1} e^{-\lambda t} \frac{(\lambda t)^n}{n!} + \sum_{n=N_{sr}+1}^{\infty} e^{-\lambda t} \frac{(\lambda t)^n}{n!} < \epsilon \] (2.7)

since all elements of \( \pi_n \) are in \([0,1]\). Fox and Glynn [5] have given a method to find \( N_{st} \) and \( N_{sr} \) given a predefined \( \epsilon \), \( \lambda \), and \( t \), and using this, SU allows solution of \( \pi(t) \) to any desired accuracy \( \epsilon > 0 \).

### 2.2 Adaptive Uniformization

In adaptive uniformization, the uniformization rate can change with the number of jumps, or current epoch, and depends on the set of states the DTMC \( X \) can be in at some epoch. The set of active states at epoch \( n \), \( n = 0, 1, \ldots \), of \( X \) is defined as \( A_n \subseteq S \) where
\[ A_n = \{ i \in S \mid \pi_n(i) > 0 \}. \] (2.8)

Then the adapted uniformization rates can be defined as \( \lambda_n \geq \max \{ q_i \mid i \in A_n \} \), for \( n = 0, 1, \ldots \) Restricted state-transition rate matrices for each step \( n \), called adapted
**infinitesimal generators** in [18], can be defined as the $Q_n = (q_n(i,j)), i, j \in S$, such that

$$q_n(i,j) = \begin{cases} q(i,j) & \text{if } i \in A_n \\ 0 & \text{otherwise} \end{cases}$$

Only rows of $Q$ corresponding to active states in each epoch are considered. Next, the **adapted transition matrices** are given by

$$P_n = I + \frac{1}{\lambda_n} Q_n, n = 0, 1, \ldots$$

(2.9)

If $U_n(t)$ is defined to be the probability of $n$ jumps in time $t$ in the birth process formed by the adaptive uniformization rates $\lambda_0, \lambda_1, \ldots$, then the transient state probability vector can be defined as

$$\pi(t) = \pi(0) \sum_{n=0}^{\infty} U_n(t) \prod_{i=0}^{n-1} P_i = \sum_{n=0}^{\infty} U_n(t) \pi_n,$$

(2.10)

where

$$\pi_n = \pi_{n-1} P_{n-1}, n = 1, 2, \ldots \text{ with } \pi_0 = \pi(0).$$

(2.11)

As with SU, the sum is truncated so that

$$\pi(t) \approx \sum_{n=0}^{N_a} U_n(t) \pi_n \text{ with } \sum_{n=N_a+1}^{\infty} U_n(t) < \epsilon.$$ 

(2.12)

Left truncation is not employed since the jump probabilities no longer form a Poisson distribution. Like SU, AU solutions can be found to any accuracy $\epsilon > 0$. Since all elements of $\pi_n$ are in $[0, 1]$,

$$\left\| \sum_{n=N_a+1}^{\infty} U_n(t) \pi_n \right\|_\infty \leq \sum_{n=N_a+1}^{\infty} U_n(t) < \epsilon.$$ 

(2.13)

By using a pure birth process to find the jump probabilities, it is possible to make probabilistically larger jumps with AU than SU. Thus, for identical $\epsilon$ and $t$, $N_a \leq N_{sr}$, potentially resulting in a reduction of computation time.
CHAPTER 3
IMPLEMENTATION DETAILS

This chapter begins with a discussion about the main difficulty of adaptive uniformization, the calculation of the jump probabilities. The three methods implemented in this study are examined first. A short explanation of the Poisson probability calculation follows while a look at the overall algorithm implementation concludes the chapter.

3.1 Jump Probability Calculation

The basic difference between AU and SU lies in calculation of the jump probabilities. For SU, the jump process has a Poisson distribution, while AU’s takes the form of a general birth process. It can be defined by $B = \{B(t); t \geq 0\}$ over the state space $S = \{0, 1, \ldots\}$. Then $U_n(t) = \text{Prob}\{B(t) = n\}$, with $B$’s infinitesimal generator matrix $Q_B$ of the form

$$Q_B = \begin{pmatrix}
-\lambda_0 & \lambda_0 & 0 & \ldots & 0 & \ldots & \\
0 & -\lambda_1 & \lambda_1 & 0 & \ldots & 0 & \ldots & \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \\
0 & \ldots & \ldots & 0 & -\lambda_{N_a} & \lambda_{N_a} & \ldots & \\
0 & \ldots & \ldots & \ldots & 0 & -\lambda_{N_{a+1}} & \ldots & \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & 
\end{pmatrix} \quad (3.1)$$
where \( \lambda_i \) is as defined in Section 2.2. For practical purposes, the infinite matrix \( Q_B \) is of course truncated to the state space \( S = \{0, 1, \ldots, N_a\} \). In the following sections, the three alternatives used in this study to compute the jump probabilities for AU, an acyclic Markov chain evaluator (ACE) developed by [28] then refined in [23], a modified ACE scheme from [18], and standard uniformization, will be discussed. Special attention will be given to issues related to their implementation in the context of having no prior knowledge of the adaptive uniformization rates.

3.1.1 ACE

ACE is applicable to solving this problem both because of \( B \)'s acyclic nature and that the ACE algorithm is recursive. The method is based upon the fact that

\[
U_n(t) = \pi_{B,i}(t) = \sum_{\zeta_j \in \Gamma} K_i(\zeta_j) \sum_{k=0}^{K_i(\zeta_j)} a_{i,j,k} t^k e^{\zeta_j t}, \text { when } n = i
\]  

(3.2)

is the general form of the transient solution of a CTMC, where \( \Gamma \) is the set of unique poles and \( K_i(\zeta_j), \zeta_j \in \Gamma \), is the number of poles with value \( \zeta_j \) in the Laplace transform expression [23]. The \( a \) coefficients are indexed by \( i, j, \) and \( k \), representing the \( i \)th state, \( j \)th unique pole, and \((k+1)\)th appearance of the \( j \)th pole. Thus \( \zeta_j \) is the \( j \)th unique pole. Calculation of \( a_{i,j,k} \) can be accomplished recursively through the method of [23] in the special case of an acyclic CTMC. In this study numerical improvements shown in [13] and [14] to reduce cancellation error and chance of overflow have been incorporated. First, the generator matrix \( Q_B = (q_B(i,j)), i,j \in S, \) is scaled by the mission time \( t \), resulting in

\[
\overline{Q}_B = tQ_B, \overline{\zeta}_j = t\zeta_j
\] 

(3.3)
and thus
\[ 
\overline{\lambda}_i = t \lambda_i = -\overline{q}_B(i, i), \text{ for } i = 0, 1, \ldots, N_a.
\]  
(3.4)

Second, we have for the initial state 0
\[ 
\overline{\gamma}_1 = -\overline{\lambda}_0, \quad K_0(\overline{\gamma}_1) = 0, \quad \overline{\pi}_{0,1,0} = e^{-\overline{\lambda}_0}.
\]  
(3.5)

Finally, the other coefficients are derived recursively by the following scheme starting with state 1
\[ 
\overline{\pi}_{i,j,k} = \begin{cases} 
\overline{\gamma}_{i-1,j,k} \frac{\overline{\lambda}_{i-1}}{\overline{\gamma}_{i-1,j} + \overline{\lambda}_i} & \text{iff } \overline{\lambda}_i \neq \overline{\gamma}_j \text{ and } k = K_i(\overline{\gamma}_j) \\ 
\overline{\gamma}_{i-1,j,k} \frac{\overline{\lambda}_{i-1}}{\overline{\gamma}_{i-1,j} + \overline{\lambda}_i} - (k + 1) \overline{\pi}_{i-1,j,k+1} \frac{\overline{\lambda}_{i-1}}{\overline{\gamma}_{i-1,j} + \overline{\lambda}_i} & \text{iff } \overline{\lambda}_i \neq \overline{\gamma}_j \text{ and } 0 \leq k < K_i(\overline{\gamma}_j) \\ 
\overline{\pi}_{i-1,j,k-1} \frac{\overline{\lambda}_{i-1}}{\overline{\gamma}_{i-1,j} - \overline{\lambda}_i} & \text{iff } \overline{\lambda}_i = \overline{\gamma}_j \text{ and } 1 \leq k \leq K_i(\overline{\gamma}_j) \\ 
- \sum_{\overline{m} \in \Gamma, \overline{m} \neq \overline{\lambda}_i} \overline{\pi}_{i,m,0} e^{-\overline{\lambda}_m - \overline{\gamma}_m} & \text{otherwise}
\end{cases}
\]  
(3.6)

Given these improvements from [13], computing \( \pi_{B,i}(t) \) from the ACE coefficients is a simple matter of summation, so
\[ 
\pi_{B,i}(t) = \sum_{\overline{\gamma}_j \in \Gamma} \sum_{k=0}^{K_i(\overline{\gamma}_j)} \overline{\pi}_{i,j,k}.
\]  
(3.7)

In the implementation the sum of Equation 3.6 (d) is calculated such that positive and negative terms are added in ascending order according to their absolute values, with the addition of these partial results being the total sum, thereby reducing cancellation error [13]. This scheme is not employed in the \( \pi_{B,i}(t) \) summation. The additional overhead is high because of ACE’s complexity, and more importantly, it would not contribute to the stability of the method. Since the coefficients for the current state’s transient probability are only dependent upon the previous state’s, ACE for this specialized type of acyclic CTMC can be implemented dynamically, with only two sets of coefficients held
in memory simultaneously. However, each new iteration adds another coefficient, making ACE an \(O(N_a^2)\) algorithm.

### 3.1.2 Modified ACE

To reduce the computational complexity from \(O(N_a^2)\) to \(O(N_a)\), [18] introduced a modified version of ACE for when \(\lambda_i\) converges to a fixed rate \(\lambda\). Convergence is typical behavior in AU and is also a by-product of all states becoming active. Although it is not necessarily the case if strict rules of adaptive uniformization are followed, this implementation designates the maximum rate \(\lambda\) to be the converged rate. As soon as the state with rate \(\lambda\) becomes active, the birth process is assumed to have converged. As will be seen, this notion of convergence is important to making adaptive uniformization computationally beneficial.

So, if convergence occurs at epoch \(m\), it can be said \(\lambda_{m+l} = \lambda\) for \(l = 0, 1, \ldots\), implying that the birth process \(B\) behaves as a Poisson process from epoch \(m\) onwards. By convolving a hypo-exponential and Poisson distribution [18], and taking into account scaling by \(t\), an equation for \(U_{m+l}(t)\) can be derived:

\[
U_{m+l}(t) = \sum_{\tau_j \in \Gamma, \tau_j \neq - \infty}^{K_m(\tau_j)} \sum_{k=0}^{K_m(\tau_j)} \sum_{r=0}^{k} b_{m,j,k}(-1)^r \frac{k!}{r!(k-r)!} \frac{\lambda^r}{(\lambda + \tau_j)^{r+l+1}} \frac{(r+l)!}{l!} e^{-\tau_j}

- \sum_{\tau_j \in \Gamma, \tau_j \neq - \infty}^{K_m(\tau_j)} \sum_{k=0}^{K_m(\tau_j)} \sum_{r=0}^{k} b_{m,j,k}(-1)^r \frac{k!}{r!(k-r)!} \frac{\lambda^r}{(\lambda + \tau_j)^{r+l+1}} \frac{(r+l)!}{l!} e^{-\tau_j} \sum_{v=0}^{r+l} \frac{(\lambda + \tau_j)^v}{v!} \tag{3.8}
\]

given that \(\lambda \neq \lambda_i\) for \(0 \leq i < m\). By creating terms \(A\), \(C\) and \(D\), \(U_{m+l}(t)\) can be computed recursively, with a constant number of operations per step. So, let

\[
A(j,k,r)(l) = b_{m,j,k}(-1)^r \frac{k!}{r!(k-r)!} \frac{\lambda^r}{(\lambda + \tau_j)^{r+l+1}} \frac{(r+l)!}{l!} e\zeta \tag{3.9}
\]
\[ C_{j,r}(l) = \sum_{v=0}^{r+l} \frac{(\bar{\lambda} + \bar{\gamma}_j)^v}{v!} \]  

for \( l \geq 0 \). Recursive relations, necessary for implementation, for \( l > 0 \) are

\[ A_{j,k,r}(l) = A_{j,k,r}(l-1) \frac{\bar{\lambda}}{(\bar{\lambda} + \bar{\gamma}_j)} \frac{(r+l)}{l} \]  

\[ C_{j,r}(l) = C_{j,r}(l-1) + D_{j,r}(l) \]

where

\[ D_{j,r}(l) = \frac{(\bar{\lambda} + \bar{\gamma}_j)^{r+l}}{(r+l)!} = D_{j,r}(l-1) \frac{(\bar{\lambda} + \bar{\gamma}_j)}{r+l} \].

Therefore, \( U_{m+l}(t) \) can be expressed more succinctly as

\[ U_{m+l}(t) = \sum_{\tau_j \in \Gamma, \tau_j \neq -\bar{\lambda}} \sum_{k=0}^{K_m(\tau_j)} \sum_{r=0}^{K} \left[ A_{j,k,r}(l) - A_{j,k,r}(l)C_{j,r}(l) \right]. \]  

In the implementation, for \( i \leq m \), \( U_i(t) \) is found via ACE. When the converged rate \( \lambda \) is encountered, values for \( A_{j,k,r}(0), C_{j,r}(0) \) and \( D_{j,r}(0) \) are calculated. The conversion [19] from \( \bar{\sigma}_{m,j,k} \) in Equation 3.6 to \( \bar{b}_{m,j,k} \) in Equation 3.8 is given by

\[ \bar{b}_{m,j,0} = (\bar{\lambda} + \bar{\gamma}_j)\bar{\sigma}_{m,j,0} \]

\[ \bar{b}_{m,j,k} = (\bar{\lambda} + \bar{\gamma}_j)\bar{\sigma}_{m,j,k} + (k+1)\bar{\sigma}_{m,j,k+1} \]

\[ \bar{b}_{m,j,K_m(\tau_j)} = (\bar{\lambda} + \bar{\gamma}_j)\bar{\sigma}_{m,j,K_m(\tau_j)} \]

Then \( U_{m+l}(t) \) for \( l > 0 \) is found from Equation 3.14 and by updating the \( A, C \) and \( D \) coefficients via Equations 3.11, 3.12 and 3.13. As can be seen, from this point onwards the computational complexity is linear, and thus Modified ACE is an \( O(N_a) \) algorithm.

Further simplification is possible when \( \lambda_i \neq \lambda_j, i \neq j \) for all \( i, j \in \{0, \ldots, m\} \). Then
\( K_m(\overline{\tau}_j) = 0 \) for all \( \overline{\tau}_j \), and the sums over \( k \) and \( r \) disappear, thus requiring less calculation per epoch. It then holds that

\[
A_j^{(1)}(l) = \overline{\theta}_{m,j,0} \frac{\overline{\lambda}^l}{(\overline{\lambda} + \overline{\tau}_j)^{l+1}} e^\lambda = \frac{\overline{\lambda}}{(\overline{\lambda} + \overline{\tau}_j)} A_j^{(1)}(l - 1) \tag{3.16}
\]

\[
C_j(l) = \sum_{v=0}^{l} \frac{(\overline{\lambda} + \overline{\tau}_j)^v}{v!} = C_j(l - 1) + D_j(l) \tag{3.17}
\]

with

\[
D_j(l) = \frac{(\overline{\lambda} + \overline{\tau}_j)^l}{l!} = \frac{(\overline{\lambda} + \overline{\tau}_j)}{l} D_j(l - 1). \tag{3.18}
\]

Finally, this gives

\[
U_{m+\ell}(t) = \sum_{\overline{\tau}_j \in \overline{\tau}} \left[ A_j^{(\tau)}(l) - A_j^{(-\overline{\lambda})}(l)C_j(l) \right]. \tag{3.19}
\]

The summation for \( U_{m+\ell}(t) \) in Equation 3.14 or 3.19 is done by adding the terms in ascending order of their magnitude, for both positive and negative numbers, then summing these two intermediary results. This reduces cancellation error, and is reasonable to implement within modified ACE because it is of order \( O(N_a) \). Since the coefficients \( A \), \( C \) and \( D \) are independent of one another, all terms can be held in a single array that is updated each jump.

### 3.1.3 Uniformization

The final method used to compute jump probabilities is standard uniformization itself.

The variant of AU that uses this is called *layered uniformization* (LU) [18]. Let \( \lambda = \max \{ \lambda_i \}, i = 0, \ldots, N_a \). Then

\[
U_n(t) = \sum_{k=N_B}^{N_{br}} e^{-\lambda t} \frac{(\lambda t)^k}{k!} \frac{B}{\overline{\tau}_k} (n), \text{ for } n = 0, \ldots, N_a \tag{3.20}
\]
where
\[ \pi^B_k = \pi^B_{k-1} P_B, \text{ with } \pi^B_0(0) = 1 \] (3.21)
and
\[ P_B = I + \frac{1}{\lambda} Q_B. \] (3.22)

As shown in Section 2, the truncation bounds \( N_{Bl} \) and \( N_{Br} \) can be selected such that the resulting truncation error is smaller than an \( \epsilon_B > 0 \). The bound on the total error from truncation in LU is then given by \( \epsilon + \epsilon_B \) [17].

In the actual implementation, \( Q_B \) is found step by step based on the set of active states, which, due to its special nature, can be stored as an array rather than a sparse matrix. Thus there exists a \( P_{B,n} \) rather than a \( P_B \), for each \( n \) such that
\[ P_{B,n} = I + \frac{1}{\lambda_k} Q_{B,n}, \text{ with } \lambda_k = \max\{\lambda_i\}, i = 0, \ldots, n. \] (3.23)

So, each state (jump) probability is calculated separately, as each new adapted uniformization rate is found. As with modified ACE, reaching the converged rate \( \lambda \) at some epoch \( m \) is an important step. Then it is assumed that \( \lambda_i = \lambda \) for \( i = m, \ldots, N_a, \ldots \) and all the rest of the jump probabilities can be found immediately via the standard uniformization in Equation 3.20. Since the converged rate is taken to be \( \lambda \), the maximum rate in the CTMC \( Y \), the vector matrix multiplication in Equation 3.21 reduces to \( \pi^B_k(n) = \pi^B_{k-1}(n-1) \) for \( n > m \). This combined with using the Fox and Glynn algorithm results in a total order of complexity of \( O(N_a \sqrt{N_{Br}}) \) [17]. Notice that a priori knowledge of all adaptive uniformization rates would reduce the total computation necessary, but not the level of complexity.
3.1.4 Summary of Methods

The three alternatives used in this study for calculation of the jump probabilities for adaptive uniformization have been discussed. Implementations for all three options were described in the context of dynamic calculation of adaptive uniformization rates, that is, new rates are found per iteration as opposed to knowing them all in advance. The issue of reducing error in ACE and Modified ACE was also addressed. Since the coefficients in these algorithms are unbounded and possibly negative, these two methods are potentially unstable. In fact, both implementations have instability checks that cause termination of the transient calculation whether accuracy demands have been met or not. However, testing is required to effectively gauge their instability. On the other hand, uniformization is inherently stable because it uses only positive, bounded elements. In terms of complexity, Modified ACE is best, followed by uniformization and then ACE. Experimental results will be given in Section 5 to compare these methods’ usefulness. Table 3.1 summarizes these three methods and the jump probability calculation for SU in terms of complexity and potential stability.

Table 3.1: Complexity and Stability of Methods
3.2 Poisson Probability Calculation

For both SU and LU, Poisson probabilities are calculated using the method of Fox and Glynn [5]. Starting with the mode, which is assigned a weight with the intent to avoid underflow, the remaining weights between the left and right truncation points are found recursively. These weights are then divided by a constant $\alpha$ to approximate the probabilities. In [5], $\alpha = W$ where $W$ is the sum of all weights within the truncation points. The result of this is that the truncated probabilities always sum to 1, and thus they err on the high side. Thus, transient state probabilities computed via SU or LU cannot be said to be an absolute lower or upper bound on the actual result.

To create a more rigorous bound, the Fox and Glynn method has been modified slightly. $\alpha$ is redefined such that

$$\alpha = W(1 + \epsilon_{LR}),$$

and define the tail masses

$$T(i) = \sum_{j=0}^{i} p(j), \quad Q(i) = \sum_{j=i}^{\infty} p(j).$$

If $L$ and $R$ are the truncation points, $\lambda$ the Poisson rate, and $m = \lfloor \lambda \rfloor$ is the mode, then $\epsilon_{LR}$ is ideally given by the bounds on the tail masses as

$$\epsilon_{LR} = T(L - 1) + Q(R + 1).$$

However, $T$ and $Q$ cannot be determined exactly, but are bounded in [5] such that

$$T(L - 1) \leq (1 + 1/\lambda) e^{1/8\lambda} \int_{-\infty}^{[m-L-1/2]/\sqrt{\lambda}} \frac{1}{\sqrt{2\pi}} e^{-s^2/2} ds$$

(3.27)
and
\[ Q(R + 1) \leq \frac{(1 + 1/\lambda)e^{1/16\sqrt{2}}}{1 - e^{-2(\lambda R - m + 1)/2}} \int_{-\infty}^{(R - m - 1/2)/\sqrt{2\lambda}} \frac{1}{\sqrt{2\pi}} e^{-s^2/2} ds. \]  
(3.28)

In the implementation, the above integrals are themselves bounded by
\[ \int_{-\infty}^{x} \frac{1}{\sqrt{2\pi}} e^{-s^2/2} ds \leq \frac{(1/\sqrt{2\pi})e^{-x^2/2}}{x}, \]  
(3.29)

with error less than \( \{(1/\sqrt{2\pi})e^{-x^2/2}\}/x^3 \) for \( x > 0 \), in order to simplify calculation. So, if \( \epsilon_{LR} \) is equated to the sum of these bounds, \( \alpha \) becomes an upper bound on the summation of the weights. Hence, dividing by \( \alpha \) to find the probabilities gives lower bound results both for the Poisson probabilities and the transient state probabilities.

### 3.3 Algorithm Implementation

Given these methods to compute the jump probabilities, this section outlines the algorithms used in the four uniformization methods considered. Inputs to the algorithms are \( t, \epsilon \), the infinitesimal generator matrix \( Q \) of the CTMC, and the initial state \( v \). LU also requires a value for \( \epsilon_B \). Both the SU and AU algorithms are given in Figure 3.1, with parts common to both methods centered. Notice that adaptive uniformization varies slightly depending upon which method is chosen to calculate the jump probabilities.

In both SU and AU, \( Q \) is read into a sparse matrix structure, holding only the non-zero elements, with \( \lambda \) found during read-in. In SU, \( P \) is calculated immediately, along with the jump probabilities \( U_{N_{\alpha}}(t), \ldots, U_{N_{\sigma}}(t) \). On the other hand, AU calculates \( U_n(t) \) on a per epoch basis from Equations 3.2, 3.14 or 3.20, except for when the converged rate is reached in LU. In that case all remaining probabilities are calculated directly from

**Figure 3.1: SU and AU Algorithms**

Equation 3.20 as outlined in Section 3.1.3. Given the nature of the AU algorithm, it can be seen without much difficulty that $Q$ could be generated as the transient solution was being found, making it applicable to unbounded state space problems. The implementation here depends on a pre-generated $Q$ from the software package *UltrSAN* [2], and thus is limited to finite state space models.
Both algorithms use loops to control the summation of Equations 2.5 and 2.12. Each iteration calculates the next $\pi_n$, then sums the product of it and epoch $n$’s probability into $\pi(t)$. From Figure 3.1, it is evident that this is a simpler process for SU, however, it is not necessarily less computationally intensive. In AU, finding $\pi_n$ from $\pi_{n-1}$ is dependent upon the adaptive uniformization rate $\lambda_{n-1}$ and whether or not the rate has converged. If the rate is unconverted, $\pi_n$ is calculated, and $\lambda_n$ is found from the new set of active states. If, on the other hand, the converged rate $\lambda$ has already been reached, $\pi_n$ is found as in SU. In this implementation, as soon as the maximum, or converged, rate in the infinitesimal generator matrix is reached, $Q$ is permanently converted to $P$ so that no repetitive computation is done.

The other main difference in the two methods is in how the main loop terminates. In SU, the end $N_{sr}$ is determined \textit{a priori} from the Fox and Glynn algorithm [5]. On the other hand, this implementation of AU finds the $\lambda_i$’s on the fly, and thus jump probabilities are calculated only an epoch at a time. These are summed iteration by iteration and checked at every update to see if the $\epsilon$ requirement has been met. Thus $N_a$ is not determined until the end of the computation. More details regarding the implementations can be found in Appendix D.
CHAPTER 4

PROGRAM INSTRUMENTATION

In order to fairly assess the accuracies and computational complexities of the different algorithms, a C++ class was developed with which the programs were instrumented. First, it enables the counting of floating point arithmetic operations by both operation type and program phase. And second, it tracks the bound on the machine round-off error for all floating point data. Thus this class is very useful for comparing numerical algorithms in terms of complexity and accuracy. Through its use of operator overloading [30], this extended double class easily instruments numerical C or C++ code, requiring only changes to the variable type declarations and output statements.

Associated with each class element are pointers to counters for addition, subtraction, multiplication and division operations. These counters are double floating point types in order to increase the count range by several orders of magnitude over unsigned long integers. Every floating point operation involving an extended double type increments the appropriate counter pointed at by the data element. For example, the statement `a = b + (c / d)` increments the addition and division counters pointed to by a, as well as updating the round-off error bound on a. By assigning different counters to variables
in different segments of the program, computational complexity can be broken down into finer algorithmic detail.

The computed data $\bar{x}$ and round-off error bound $b$ are stored as double floating point types in each element of the class, such that the true $x$ must lie in the range $\bar{x} \pm b$. The bound $b$ is not related to approximations due to the algorithm in use, but is only a bound on the machine round-off error based on the previous computations necessary to find $\bar{x}$. Initial round-off error is determined by the machine precision as a default, although external values can be assigned. For a given arithmetic operation, $b$ is propagated as follows

For $\bar{x}_r = \bar{x}_1 + \bar{x}_2$, $b_r = b_1 + b_2$  \hfill (4.1)

For $\bar{x}_r = \bar{x}_1 - \bar{x}_2$, $b_r = b_1 + b_2$  \hfill (4.2)

For $\bar{x}_r = \bar{x}_1 \times \bar{x}_2$, $b_r = b_1\text{abs}(\bar{x}_2) + b_2\text{abs}(\bar{x}_1) + b_1b_2$  \hfill (4.3)

For $\bar{x}_r = \bar{x}_1 \div \bar{x}_2$,

$$b_r = \begin{cases} \max \left\{ \text{abs} \left( \frac{\bar{x}_1}{\bar{x}_2} - \frac{(\bar{x}_1-b_1)}{(\bar{x}_2+b_2)} \right), \text{abs} \left( \frac{(\bar{x}_1+b_1)}{(\bar{x}_2-b_2)} - \frac{\bar{x}_1}{\bar{x}_2} \right) \right\} & \text{if } \bar{x}_1 \times \bar{x}_2 \geq 0 \\ \max \left\{ \text{abs} \left( \frac{\bar{x}_1}{\bar{x}_2} - \frac{(\bar{x}_1+b_1)}{(\bar{x}_2+b_2)} \right), \text{abs} \left( \frac{(\bar{x}_1-b_1)}{(\bar{x}_2-b_2)} - \frac{\bar{x}_1}{\bar{x}_2} \right) \right\} & \text{if } \bar{x}_1 \times \bar{x}_2 < 0 \end{cases}$$  \hfill (4.4)

where $\text{abs}(\bar{x})$ is the absolute value of $\bar{x}$ and $\max\{\}$ returns the maximum of its arguments. This method provides an upper bound [29] estimate on the error accumulated due to machine round-off, but cannot be considered completely rigorous because the bound computations themselves are subject to round-off error. In the next chapter results based upon this class will be given.
CHAPTER 5

RESULTS

In this chapter, three models are discussed and used for comparison of the methods. First, these models are described in the context of SAN modeling and their AU attributes, followed by a listing of the goals of this chapter. These include comparison of each method’s stability, an illustration of the operation counting $C++$ class, and finally, an evaluation of AU and SU’s performance.

5.1 Example Markov Models

To study the viability of AU, and to illustrate the code instrumentation, three example models are used. The first is an extended machine-repairman (EMR) model with repair delayed. It is a kind of reliability model particularly well-suited for solution by AU, and can easily be extended in terms of state-space size and its jump process by varying parameters. The last two are reliability models of real systems with repair. One is a fault-tolerant parallel computer system with several layers of redundancy while the other is a distributed database architecture. These systems and their associated parameters will be explained in greater detail in the following sections, while the formal documentation
for their *UltrSAN* models can be found in the appendices. A final section tabularizes the resulting adaptive uniformization rates of the models.

### 5.1.1 EMR Model

The EMR model is similar to ones given in [3] and [31]. In this model there are $K$ components, all with the same failure rate, $\rho$. There are two classes of failure, *hard* and *soft*, where the probability of a failure being soft is $c$ and that of a hard failure $1 - c$. $c$ is known as the *coverage factor*. Repair begins when only $r$ components remain functional, with repairs taking place at a rate of $\mu$ for a hard failure and $\nu$ for a soft failure, with $\nu > \mu$ typically. The failures and repairs are all negative exponentially distributed in time with $\rho$, $\mu$ and $\nu$ as parameters. Each component has independent repair capability, and repair continues until all units are operational. Correct service is provided whenever at least one component is functional. Usually $\mu, \nu \gg \rho$, and thus there are a number of epochs with low adaptive uniformization rates followed by higher rates and the converged rate.

For this study, two sets of models with a range of $K$ values and constant $r, \rho, \mu, \nu$ and $c$ have been chosen. Notice that $c$ has no effect on the state space size, assuming $c$ is in $(0,1)$, and that the adaptive uniformization rates are a function of $K$, $r$, $\rho$ and $\max\{\mu, \nu\}$. Also, the converged rate $\lambda = (K - 1)\max\{\mu, \nu\} + \rho$. For the first set $K = 20$ or 50, $r = 10$, $\rho = 1$, $\nu = 1000$, $\mu = 800$ and $c = 0.5$. Thus while $\mu$ and $c$ may effect the reliability, they do not effect the computation time in the discussed algorithms. The second set consists of larger models, where $K = 200, 250$ or 300, $r = 100$, $\rho = 1$, $\nu = 100$, 
\( \mu = 80 \) and \( c = 0.5 \). For all LU results, \( \epsilon_B = 10^{-14} \), whereas parameter \( \epsilon \) is varied along with \( t \) as part of the experiment. Mission times \( t \) on the order of \( 1/\rho \) were used, the mean time of a component failure, which is reasonable for highly reliable applications [18]. A typical measure of interest in this model is then system reliability, or the probability of at least one unit functioning.

5.1.2 Fault-Tolerant Parallel Computer System Model

A more realistic test-model is a fault-tolerant multiprocessor system (FTPCS) originally given in [12], and modeled with UltraSAN in [26]. The version here has been modified slightly to include delayed repair and greater redundancy, and is shown in Figure 5.1. The system consists of two computers, each composed of four CPU units, two of
which are spare, three memory modules, one of which is spare, three I/O ports with two redundant, and three error-handlers, two of which are spare. In addition, each memory module has 40 RAM chips, one of which is spare, and two sets of interface chips with one set spare. Repair only takes place when an entire computer has failed, with total system failure occurring when both computers have failed. In Figure 5.1, all spare units are indicated with dashed lines.

Two varieties of the model were used in this study, one with perfect coverage, i.e., spares cover failures 100% of the time, and the other with non-perfect coverage. The coverage factors are given in Table 5.1, and are an extension of those from [12]. Finally, the chip failure rate is assumed to be 100 failures per billion hours, as in [12], with a negative exponential distribution. Parts with multiple chips have failure rates in proportion to their chip count. Repair is also assumed to occur with an exponential distribution, with a mean of 0.001 years. Mission times of interest are on the order of years.

Table 5.1: Coverage Factors for FTPCS
5.1.3 Distributed Database Model

The last example is a distributed architecture for a database system (DDA), based on a model from [26], which was itself modified from [21, 22]. The system consists of four disk clusters, two sets of controllers, and three processors as depicted in Figure 5.2. A disk cluster has five disks, with information redundant between them such that any two can fail without loss of data access. A disk controller set consists of three controllers, at least one of which must be functioning. The system is then operational when all clusters are fully accessible through at least one controller by at least one of the three processors, and coverage factors are not considered here. Repair for the different components is independent. Repair on a disk cluster begins when two disks have failed, and controllers and processors are repaired when two of three in a set have failed. All redundant components are shown with dashed outlines in Figure 5.2. Table 5.2 gives
failure and repair rates per hour for the database system components. Mission times of interest are on the order of weeks.

</tr>
</tbody>
</table>

Table 5.2: Per Hour Failure and Repair Rates

5.1.4 Adaptive Uniformization Rates

Since the adaptive uniformization rates form the jump process, they play a key role in determining how beneficial AU is. Table 5.3 lists the rates for each model, $\lambda_0$ through $\lambda_m = \lambda$, along with $m$ values. Therefore, the last rate in each column is the maximum and converged rate for each system.

5.2 Goals of Results

Several aspects of the results will be discussed. First, the accuracy of the different methods will be compared in terms of their resulting bounds on the round-off error. Second, an illustration of operation counting in the instrumented code will be given. Finally, the computational complexity of the algorithms are compared. Two methods of comparison are used, computation time (CPU usage) and number of floating point operations. Since all AU algorithms have a higher order of complexity in computing jump probabilities than SU with respect to time, the results exhibit crossover points $t'$, where AU is less computationally complex for $t < t'$ and SU performs better for $t > t'$,
Table 5.3: Adaptive Uniformization Rates of the Example Models

whenever $N_a < N_{sr}$. The crossover point based on computation time is designated $t_T$, while the floating point operation crossover time is labeled $t_F$. The two measurements will show slight differences because some overhead is not accounted for by operation counts, and the operation type distribution varies between SU and AU.
5.3 Comparison of Method Stability

Both SU and LU are numerically stable owing to their use of probability matrices with positive, bounded elements, and the Fox and Glynn method to calculate Poisson probabilities, while ACE and Modified ACE are not guaranteed to be stable. The limitations of these algorithms will be looked at first through the use of the C++ class. The round-off error results are from system reliability, and are normalized. By this it is meant that for a given time $t$, the round-off bound $B_r(t)$ of system reliability $R(t)$ is normalized to $B_r(t)/R(t)$. Thus the round-off errors shown are relative to $1.0$, i.e.

$$1.0 - \frac{B_r(t)}{R(t)} \leq \frac{R(t)}{R(t)} \equiv 1.0 \leq 1.0 + \frac{B_r(t)}{R(t)},$$

(5.1)

where $B_r(t)/R(t)$ is the actual data used in all stability plots. This enables fair comparison over a range of $t$ and $R(t)$ values. As can be seen in Figure 5.3, the accuracy of both ACE and Modified ACE is limited. The tests for Figure 5.3 were run on the $K = 20$ EMR model with the requirement $\epsilon = 10^{-1}$, and yet the bounds on the resulting round-off error were often orders of magnitude larger than this for a large range of $t$. Other EMR models with different $K$ values, and smaller $\epsilon$ requirements, showed worse performance, even to the point where any viable solution was unattainable.

In order to get a better picture of ACE and Modified ACE stability, data has been collected from the other two models as well. In Figure 5.4, plots with differing time points are shown in terms of error bound versus desired accuracy, $\epsilon$, for the Distributed Database Architecture model. Performance degrades rapidly both in terms of increasing time and decreasing $\epsilon$ for AU with ACE, as both of these factors cause an increase in the necessary
truncation point and number of jump probabilities to be calculated. In fact, the missing points in the AU with ACE plots have round-off errors outside the scale of the graph. Modified ACE recorded the exact same results as ACE because the converged rate was never reached.

Of all models used, FTPCS with perfect coverage was best suited to solution via AU with ACE or Modified ACE, as depicted in Figure 5.5, where once again, round-off error is normalized by system reliability. In particular, Modified ACE shows good stability for a large range of $t$ and fairly small $\epsilon$. Further study, however, shows that even for this model, ACE and Modified ACE methods are limited compared to LU. Figure 5.6 is a graph of truncation point, or number of iterations until termination, versus decreasing

Figure 5.3: Reliability Round-off Error Bounds: $K = 20$, $r = 10$, $\epsilon = 10^{-4}$
Termination occurs when either accuracy demands are met or instability detected. Instability is said to have occurred when either the computed jump probabilities fall outside [0,1], or the summation of all these probabilities comes to greater than 1. It can be seen that as $\epsilon$ drops below $10^{-6}$, the curves for ACE and Modified ACE incorrectly flatten out to a slope of zero, indicating their inability to solve to very high accuracies because numerical instabilities cause premature termination. LU does not suffer from this drawback. Thus, due to the limited and unpredictable capabilities of the ACE and Modified ACE algorithms, they are probably not useful for general implementations of adaptive uniformization. Therefore, the remaining performance results focus on the LU variant of AU.
Figure 5.5: FTPCS Model: Round-off Error vs. Time

Figure 5.6: FTPCS Model: Iterations vs. $\epsilon$
On the other hand, SU and LU show good results in terms of numerical stability, with similar results found over a wide range of models and \( \epsilon \) values as demonstrated in Figures 5.3 and 5.4. LU shows better performance than SU in Figure 5.3 for small \( t \), and in Figure 5.4, simply because fewer calculations were necessary to achieve the result. Note that the truncation error in SU can be made arbitrarily close to 0 through the use of Fox and Glynn’s algorithm for computing Poisson probabilities. However, making \( \epsilon \) less than the machine’s epsilon, i.e., the smallest number \( x \) such that \( 1.0 + x \neq 1.0 \), has little value. LU’s truncation error is limited by this machine epsilon, since a running total sum of the jump probabilities is used to detect when to truncate. A specified \( \epsilon \) less than the machine epsilon would not allow the infinite sum to truncate.

5.4 Illustration of Operation Counting

This section shows results to illustrate use of the instrumentation method to count operations. Figure 5.7 shows a breakdown by operation type for a 50 component EMR model. The operation types are important because their individual computational complexities vary from machine to machine, and thus comparisons may want to take this into account. In this example it can be seen that additions and multiplications dominate the divisions and subtractions in both the SU and LU algorithms. However, the operation distributions are not the same, as LU requires a larger percentage of subtractions and divisions for solution. The operation crossover point in computational complexity can be seen to lie somewhere between \( t = .6 \) and \( t = .8 \).
In Figure 5.8 the counts are divided between the different aspects of the algorithm that contribute to the computational complexity:

- **INIT**: Operations done during the read-in of $Q$.
- **JPR**: Computation of jump probabilities $U_n(t)$.
- **QP**: Calculation of $P$ and/or $P_n$.
- **MVM**: Matrix vector multiplication $\pi_{n-1}P$ and/or $\pi_{n-1}P_{n-1}$.
- **SOL**: $\pi(t) + \pi_n U_n(t)$ calculation.
The time $t = .6$ was selected because total computational complexity is almost equal at this time, allowing fair comparison. The histogram clearly shows the trade-off between the two methods. LU trades increased computational complexity in calculating the jump probabilities (JPR) for a reduction in the number of matrix vector multiplications (MVM), as compared to SU. The latter follows from the fact that LU truncates earlier because the adaptive uniformization rates allow it to make probabilistically larger jumps. Note that since the scale is logarithmic, the difference in MVM complexity is actually greater than the difference in JPR. LU also shows increased activity in QP since $P_n$ is calculated multiple times and in SOL because LU does not left truncate.
5.5 Comparison of AU and SU

The next two figures demonstrate the computational advantages of LU, as well as illustrate the two kinds of crossover points using the EMR model. Larger state space-sized models with $K = 200, 250, 300$ and $r = 100$ were selected to show AU and SU’s ability to solve very large problems. Figure 5.9 depicts the computational complexity in terms of the total number of floating point operations. Within these results, all operation types are given equal value. For a given machine these operations could easily be weighted to reflect their individual computational intensities. It can be seen that $t_F$, the operation crossover point, occurs at approximately $t = 1.9$. For $t < .5$, the converged rate has not been reached when the truncation point occurs, and thus it can be seen that savings of about 2 orders of magnitude are reaped for this particular model. The large jump in complexity at $t \approx .5$ occurs when the converged rate is reached, and no further savings are possible.

A graph of computation time on a Sparcstation 10/30 versus time $t$ is given in Figure 5.10. The $t_F$ occurs at slightly less than $t = 2$. This shows that the extra complexity in the LU algorithm has little to no effect on the overall computation time. Also note that the savings for $t < .5$ are less in terms of time because operation counts do not reflect computational time spent on matrix read-in, etc. If, for example, the matrix were passed directly from the CTMC generator, this would not be a factor. The rest of the results will be based upon instruction counts, since these are reliable, and repeatable across hardware and software platforms. CPU usage is not the most dependable measure since
Figure 5.9: Operations vs. Time: $K = 250, r = 100, 42700$ states, $\epsilon = 10^{-8}$

Figure 5.10: CPU Usage vs. Time: $K = 250, r = 100, 42700$ states, $\epsilon = 10^{-8}$
it can be unpredictably influenced by concurrent execution of the operating system and other application programs.

In order to see that the two algorithms, LU and SU, have different orders of complexity in terms of big-$O$ notation, Figure 5.11 is given. This EMR model is not particularly amenable to LU solution because of its small state-space size and lesser number of unconverged rates. However, these same factors enable solution over a large time scale, allowing general complexity trends to be seen. It is evident that SU is linear with respect to time, while LU is of higher order. In fact, it is the jump process calculation with complexity
that dominates and gives LU its upwardly curving shape. Still, there exists a crossover point $t_F$, at approximately $t = .15$.

Figure 5.12 gives results for the two FTPCS models. The model of the system with perfect coverage has 23,653 states, while the non-perfect coverage model has 23,869 states and a denser transition matrix. From the graph, the former has a crossover point between 6 and 7 years, while the latter’s $t_F$ is almost at 3 years. The model with perfect coverage does better since the jump process has more unconverged rates (see Table 5.3). Non-perfect coverage removes the delayed repair aspect from the solution’s point of view. The effect of this is more evident in Figure 5.13. The model with non-perfect coverage never shows truly substantial savings because it only has a single unconverged rate, whereas for perfect coverage the time of interest $t$ must be greater than 0.1 years for the converged rate to be reached. The flatness for the LU graph of FTPCS with perfect coverage, for $t \leq 0.1$, is attributable to its small number of unconverged rates, making further savings minimal.

The third model, the distributed database architecture, is used for comparison in Figure 5.14. It is an 8,260-state model, with a crossover point $t_F$ at a little less than 1 week. Figure 5.15 compares SU and LU for smaller mission times. The point at which convergence occurs is not very clear in Figure 5.15 since many of the unconverged rates have values close to the converged one. Finally, notice in Figures 5.12 through 5.15 that LU does not have the orders of magnitude savings it has for EMR models. This is because with their small number of unconverged rates and lower converged rate, $N_n$ and $N_{sr}$ differ by less. However, while these models do not show as impressive of savings, they do show
Figure 5.12: Complexity vs. Time: FTPCS Model, $\epsilon = 10^{-6}$

Figure 5.13: Complexity vs. Time: FTPCS Model, $\epsilon = 10^{-6}$
Figure 2.14: Complexity vs. Time: DD Model, $c = 10^{-6}$
Figure 5.16: Complexity vs. Time: EMR Models with $\epsilon = 10^{-8}$

larger ranges of $t$ for which savings exist. Also, further redundancy, perhaps necessitated by greater reliability needs, would improve the profitability of LU.

The computational complexity versus the time parameter for three different EMR models of varying state space size is shown in Figure 5.16. This graph depicts how increased state space size increases $t_F$ because a reduction in the number of vector matrix multiplications becomes a more important factor. $t_F$ rises from less than 1.2, to approximately
Figure 5.17: Complexity vs. Time: $K = 250, r = 100, \epsilon = 10^{-4}, 10^{-8}, 10^{-12}$

1.8, and finally to just under 2.5 for the 65250-state model. Note that this effect on $t_F$ is reduced to some extent since as the state space size scales, so does its maximum, or converged rate, which has a greater effect on LU jump probability calculation than for SU.

Figure 5.17 illustrates how the requested truncation error limit affects the computation. Obviously, SU is insensitive to accuracy demands. This is because the Poisson distribution
approaches zero rapidly in either tail, making the amount of truncation differ little with changes in $\epsilon$. The distribution of the jump probabilities decreases much more slowly from its maximum in LU due to the jump process' higher variance, and therefore changes in $\epsilon$ significantly effect the truncation point $N_a$ and thus the computational effort needed for solution. Therefore, it is seen that for $\epsilon = 10^{-4}$, $t_F \approx 2.1$, while for $\epsilon = 10^{-8}$, $t_F$ is about 1.9 and for $\epsilon = 10^{-12}$, $t_F \approx 1.7$. 
CHAPTER 6
CONCLUSIONS

Many methods have been proposed to compute the transient state occupancy probabilities in continuous-time Markov chains, but no method has proven best for all models and time points of interest. Uniformization is popular, but results in extremely long run times to achieve acceptable accuracy when models are stiff. Adaptive uniformization has been proposed to alleviate these problems for some models. In this thesis, the efficiency and stability of three implementations of AU were compared to that of standard uniformization. The efficiency and stability is compared by instrumenting the code using a C++ class. This class was developed to track the bound on the round-off error incurred during the computation, as well as its computational complexity, measured in number of floating point operations. Operation counts can be refined by operation types and the algorithm phase in which they occur. The class is general, and can instrument other numerical algorithms written in C or C++ code with minimal effort.

The three adaptive uniformization implementations studied differ in the method by which they compute the jump probabilities. Of the three methods, ACE has the highest order of complexity, but is theoretically applicable to any jump process resulting from AU. Modified ACE has the least complexity, but can only be used when and if a converged
rate exists. Standard uniformization is the third method, hence the name layered uniformization for this AU variant. LU’s order of complexity falls between the two previous methods, and because of its probabilistic nature, is numerically stable. Comparing the AU alternatives with SU via our instrumented code, the methods based on ACE and Modified ACE were found not very useful because of their high round-off errors. Although not investigated, it is possible that these methods could be improved, for instance, by aggregating close-valued poles into a single pole value, avoiding some cancellation error problems. Computation of the jump probabilities in AU via uniformization resulted in small round-off errors which were, in fact, smaller than those for SU for many time points of interest, since the number of operations performed was smaller.

Comparisons of computational efficiency of the methods were limited to LU and SU due to the severe round-off errors exhibited by ACE and Modified ACE. With regard to these methods, it was found for short mission times in extended machine-repairman models that AU was orders of magnitude better than SU. For large time points, however, AU is less attractive than SU, due to its higher overall complexity. The two algorithms thus exhibit a “crossover point” where, on one side, AU is better than SU, and on the other, SU better than AU. The time crossover point $t_T$ was found to be very close to the time crossover point $t_F$, demonstrating the viability of the operation counts. Studies of varying size models showed that AU’s performance improves significantly with larger state spaces, as the reduction in the number of matrix vector multiplications becomes more important. Finally, it was shown that the computational cost of AU is more sensitive to the desired accuracy than is SU. Thus choosing a lower accuracy with AU will reduce run time more
significantly than in SU. Furthermore, like SU, AU with uniformization to compute the jump probabilities is stable and exhibits very low round-off errors for the models studied. These results suggest applications that could benefit directly from adaptive uniformization and, due to the crossover point, suggest that AU could profitably be combined with other methods. In particular, a solver may be buildable that estimates the crossover point, and selects the best method given the mission time. Thus multiple methods might be combined to achieve more efficient solutions than any single method (see [15]). Further study is necessary to determine if and when these hybrid approaches would be advantageous.
APPENDIX A EMR Model Documentation

In order to derive the continuous-time Markov chains necessary to test the algorithms, the modeling tool UltraSAN [2] was used. From a graphical description, UltraSAN generates the state space of a CTMC from the SAN description.

The SAN for the EMR model is given in Figure A.2, and consists of five kinds of components: places (circles), timed activities (elongated ovals), an instantaneous activity (vertical bar), input gates (triangles pointing left), and output gates (triangles pointing right). The activities represent delays and events in the system. Timed activities require a non-negligible time to complete, and for a SAN to represent a CTMC, this time must be exponentially distributed. Instantaneous activities require no time, and complete upon activation. Both of these components can have cases, represented graphically by attached small bubbles. They allow different events to occur upon activity completion with some user-defined probability.

Places hold tokens. In the EMR model, the tokens in the place working represent operational units. The number of tokens in a place is called the marking of the place. The $MARK()$ macro returns the marking of a place, and is an extension of the C code that is used to define that attributes of the SAN components.

Input gates have an enabling function, or predicate, and a function. The predicate is defined by the places to which it is connected, and when true, enables the activities to which it is connected. Upon activity completion, the function is executed, allowing changes to markings of connected places. Output gates have only a function, which is executed when its governing activity completes.
The following three appendices give documentation for the three example models based on the above.

APPENDIX B FTPCS Model Documentation

This appendix gives the model documentation for fault-tolerant parallel computer system with both perfect and non-perfect coverage.

B.1 FTPCS with Perfect Coverage

Documentation for Composed Model: FTPCS.

![Diagram](image)

Figure B.1: Composed Model: FTPCS

The composed model for the FTPCS, Figure B.1, contains a Rep node. This allows replication of a submodel, and can reduce the resulting state space size by exploiting symmetries [27]. Interaction occurs through common places, as listed in Table B.1. Making places repair_flag and comp_failed common allows all computers in the set to know when repair is taking place and when the system has failed.

APPENDIX C DDA Model Documentation

Documentation for Composed Model: *DDA*.

![Diagram]

**Figure C.1: Composed Model: DDA**

In addition to Rep nodes, the DDA composed model in Figure C.1 has Join nodes. These allow two differing submodels to be joined with one or more common places. In this case *system_failure* is made common to all SANs.

**Table C.1: Composed Model Rep Node Definitions for Project DDA**

APPENDIX D Solver Details

This appendix covers UltraSAN organization and where these solvers fit into the heirarchy, followed by a listing of the transient solver options, or program flags, in the first two sections. The next two sections detail solver inputs and outputs. Flow diagrams for the solvers are given in the final Appendix D section.

D.1 UltraSAN Organization

As can be seen in Figure D.1, the UltraSAN software package consists of four levels. These levels correspond to the process flow of modeling. The work done here fits into the solution portion of UltraSAN, at the bottom of Figure D.1. At this time, only standard uniformization is directly accessible from the UltraSAN control panel.

D.2 Solver Options

All the implementations are compatible and have the following options:

\texttt{trs\_su}
\texttt{trs\_lu}
\texttt{trs\_ace}
\texttt{trs\_modace} [-P project name] [-S study] [-E experiment] [-o output file] [-d debug file]
[-C count operations] [-a truncation \( \epsilon \)] [-b LU jump process truncation \( \epsilon_B \)]
[-v verbosity] [-t time point, -t time point, …]

[-P project name] The character string representing the project name. A name must be specified and no default is assumed.

[-S study] The character string representing the study name. A name must be specified and no default is assumed.

[-E experiment] The character string representing the experiment name. A name must be specified and no default is assumed.

[-o output file] A character string representing the output filename. The default is stdout.
Figure D.1: UltraSAN Organization and Dataflow
[d debug file] A character string representing the debug filename. The default is no debug file.

[-C count operations] This flag enables the operation counting and bound on round-off error. The output is modified by this flag to include operation counts and round-off error bounds on the performance variables.

[a truncation ϵ] An integer x such that $\epsilon = 10^{-x}$. x represents the number of digits of accuracy desired. The default is six. If x causes $\epsilon$ to be less than the machine accuracy, the machine accuracy becomes the default.

[b LU jump process truncation $\epsilon_R$] An integer y such that $\epsilon_R = 10^{-y}$. y determines the amount of truncation done during uniformization of the jump process. The default is $y = 14$.

[v verbosity] An integer that determines how often status information is printed during computation. The integer corresponds to the number of interactions between a status update, which consists of outputting the total number of iterations completed. When the -C option is on, AU versions output the jump process rates until convergence.

[t time point] A double representing a time point of interest. Multiple time points can be specified, but as a minimum, at least one must be included as there is no default.

D.3 Solver Input

All four implementations use two input files. The first contains a representation of the CTMC. It is called a reduced base model [27] and is created by UltraSAN. The other contains the associated performance variable information. Both files are ASCII, and are pointed to by the project, study, and experiment name. Note that states are labeled \{1,2,...\} rather than \{0,1,...\} since 0 is used as a delimiter.

Reduced Base Model File Format

[unsigned long integer] // initial state label
[unsigned long integer] // total number of states
[unsigned long integer] // state A label
[unsigned long integer] // next state A1 from state A
[double] // rate to A1 from A
[unsigned long integer] // next state A2 from state A
[double] // rate to A2 from A
.
.
0 // end of transitions from A
[unsigned long integer] // state B label
[unsigned long integer] // next state B1 from state B
[double] // rate to B1 from B
[unsigned long integer] // next state B2 from state B
[double] // rate to B2 from B
.
.
0 // end of transitions from B
[unsigned long integer] // state C label
.
.
(continues until all states and their transitions have been defined)

Performance Variable Information File Format

[character string] // performance variable name #1
[character string] // performance variable name #2
.
.
[character string] // performance variable name #n
[unsigned long integer] // state A label
[double] // impulse reward for state A, pv #1
[double] // rate reward for state A, pv #1
[double] // impulse reward for state A, pv #2
[double] // rate reward for state A, pv #2
.
.
[double] // impulse reward for state A, pv #n
[double] // rate reward for state A, pv #n
[unsigned long integer] // state B label
[double] // impulse reward for state B, pv #1
[double] // rate reward for state B, pv #1
[double] // impulse reward for state B, pv #2
[double] // rate reward for state B, pv #2
.
.

[double]                      // impulse reward for state B, pv #n
[double]                      // rate reward for state B, pv #n
[unsigned long integer]      // state C label

(continues until all states and their rewards have been defined)

D.4 Solver Output

The following sample output came from executing:

trs_lu -PEMR50 -Sstudy1 -Eexp1 -C -a12 -t0.6
